Abstract

Automated deduction in higher-order program calculi, where properties of transformation rules are demanded, or confluence or other equational properties are requested, can often be done by syntactically computing overlaps (critical pairs) of reduction rules and transformation rules. Since higher-order calculi have alpha-equivalence as fundamental equivalence, the reasoning procedure must deal with it. We define ASD1-unification problems, which are higher-order equational unification problems employing variables for atoms, expressions and contexts, with additional distinct-variable constraints, and which have to be solved w.r.t. alpha-equivalence. Our proposal is to extend nominal unification to solve these unification problems. We succeeded in constructing the nominal unification algorithm NomUnifyASC. We show that NomUnifyASC is sound and complete for these problem class, and outputs a set of unifiers with constraints in nondeterministic polynomial time if the final constraints are satisfiable. We also show that solvability of the output constraints can be decided in NEXPTIME, and for a fixed number of context-variables in NP time. For terms without context-variables and atom-variables, NomUnifyASC runs in polynomial time, is unitary, and extends the classical problem by permitting distinct-variable constraints.

Keywords and phrases automated deduction, nominal unification, lambda calculus, functional programming

Introduction

Automated deduction in higher-order program calculi, where properties of transformation rules are demanded, or confluence or other equational properties are requested, can often be done by syntactically computing overlaps (critical pairs) of reduction rules and transformation rules. Since higher-order calculi have alpha-equivalence as fundamental equivalence, the reasoning procedure must deal with it. We define ASD1-unification problems, which are higher-order equational unification problems with variables for atoms, expressions, and contexts, with additional distinct-variable constraints, and which have to be solved w.r.t. alpha-equivalence. Our proposal is to extend nominal unification to solve these unification problems. The appeal of classical nominal unification is that it solves higher-order equations...
Nominal Unification with Contexts

modulo α-equivalence in quadratic time and outputs at most a single most general unifier [36, 6, 17].

Our intended application is the diagram-method, which is a syntactic proof method (e.g. [37, 12, 33]) to show properties like correctness of program transformations. As an example consider the reduction rule (cp) in the call-by-need lambda-calculus with let (see e.g. [2, 23, 33]) \( \text{let } x = \lambda y. S \text{ in } C[x] \rightarrow \text{let } x = \lambda y. S \text{ in } C[y, S] \) with the restriction that \( x \) is not bound by context \( C \). The diagram-based proof method for correctness of program transformations computes possible overlaps of the left-hand side (and in certain cases also of the right-hand side) of a program transformation with the left-hand sides of the reduction rules. An example equation is \( \text{let } A_1 = \lambda A_2. S_1 \text{ in } D_1[\lambda A_2. S_1] \rightarrow \text{let } A_3 = \lambda A_4. S_2 \text{ in } D_2[A_3] \) where \( A, S, D \) are variables standing for concrete variables (called atoms), expressions, and contexts, respectively. The equation comes together with constraints on possible occurrences of atoms, which can be formulated using the distinct-variable condition (DVC) [5, 2].

A generalized situation for overlap computation is represented by the equation \( R[\ell] = C[\ell'] \), where \( R \) is a reduction context (in which reduction takes place), \( \ell \) is a left hand side of a reduction rule, \( C \) an arbitrary context, and \( \ell' \) is the left hand side of a transformation rule. Provided \( R, C \) are variables for reduction contexts and general contexts, respectively, solving the unification equation \( R[\ell] = C[\ell'] \) can be attacked by using nominal unification in the extended language. The proposal of [31] to solve such problems w.r.t. syntactic equality permits an even higher expressiveness of the language, but the support for alpha-equivalence reasoning is missing, and hence several variants of extra constraints are necessary and further reasoning needs a technically detailed analysis of renamings [29].

Results. A sound and complete algorithm \textsc{NomUnifyASC} for nominal unification of ASD1-unification problems is constructed. The algorithm \textsc{NomUnifyASC} computes in NP time a solution including a constraint (Thm. 5.9) and the collecting version produces at most exponentially many outputs. The algorithm \textsc{NomFreshASC} that checks satisfiability of the constraints of a solution runs in NEXPTIME (Proposition 5.8), hence solvability of ASD1-unification problems can be decided in NEXPTIME (Thm. 5.10). Since the number of context-variables is the only parameter in the exponent of the complexity, we obtain that if the number of context-variables is fixed, then the algorithm \textsc{NomUnifyASC} runs as a decision algorithm in NP time.

For computing diagrams (in the diagram method), it is important to obtain a complete set of unifiers. We expect that exponentiality of the number of unifiers is not a problem, since the input is usually very small. For example, the rules of the let-calculus [2] need only one context variable. We show that DVCs are a proper generalisation of freshness constraints if combined with solving equations (Proposition 3.8). A technical innovation is that decomposition for lambda-bindings can be extended to an arbitrary number of nested lambda-bindings thanks to the DVC (see Remark 3.4, Proposition 3.5, and Example 3.6).

Classical nominal unification is generalized by replacing freshness constraints by DVC-constraints such that unitarity and polynomial complexity still hold (Thm. 6.1).

Previous and Related Work. Nominal techniques [27, 26] support machine-oriented reasoning on the syntactic level supporting alpha-equivalence. Nominal unification (syntactically presented) lambda-expressions was successfully attacked and a quadratic algorithm was developed [36, 6, 17] where technical innovations are the use of permutations on the abstract level and of freshness constraints. The approach is used in higher-order logic programming [8], and in automated theorem provers like nominal Isabelle [34, 35].

There are investigations that extend the expressive power of nominal unification problems: The restriction that bound variables are seen as atoms can be relaxed: Equivariant unification
[7, 10] permits atom-variables and permutation-variables which however, appear to add too much expressive power as mentioned in [7, 10]. A restricted language (allowing atom-variables, but without permutations at all) and its nominal unification is analyzed in [16]. An investigation of nominal unification with atom-variables and a lazy-guessing algorithm is described in [32, 15]. Nominal unification for a lambda-calculus with function constants and a recursive-let is developed in [30] and shown to run in NP time. Reasoning on nominal terms in higher-order rewrite systems and narrowing as a general, but not provably efficient method for unification is described in [4]. Nominal techniques to compute overlaps w.r.t. all term positions are in [3], but there are no context-variables and reduction strategies cannot be encoded. If there are no binders, then the problem statement can be generalized to first-order terms with arbitrary occurrences of context-variables and the unification problem is in PSPACE [14].

Classical nominal unification is strongly related to higher-order pattern unification [9, 18, 22, 28, 24] which is a decidable fragment of (undecidable) higher-order unification [13] and has most general unifiers (i.e. is unitary). A slight extension to pattern unification that is unitary and decidable is described in [19]. Another line of research for reasoning with binders is the foundation of higher-order abstract syntax [25], and extensions of higher-order pattern unification as in [1], which, however, cannot adequately deal with ASD1-unification problems, the problem class of NomUnifyASC. The use of deBruijn indices [11] has some advantages in representing lambda expressions and avoids alpha-renamings, but is not appropriate for our problem, since we have to deal with free variables and with context variables that may capture variables.

Outline. Sect. 2 contains the definitions and extensions of nominal syntax. In Sect. 3 the preparations for the nominal unification algorithm are done, and in Sect. 4 the algorithm NomUnifyASC is introduced, which consists of a set of (non-deterministic) rules, and also the constraint checking algorithm NomFreshASC. In Sect. 5 the properties of the algorithms are analyzed. In Sect. 6 the special case NL aS is reconsidered, and we illustrate how the unification algorithm operates on examples. We conclude in Sect. 7. Most of the proofs are omitted in the main part, but given in the appendix.

2 Nominal Languages and Nominal Unification

We explain the nominal (meta-)languages representing higher-order languages, their semantics and also several operations.

Let \( F \) be a set of function symbols where each \( f \in F \) has a fixed arity \( \text{ar}(f) \geq 0 \), and \( F \) contains at least two function symbols, one of arity 0 (a constant) and one of arity \( \geq 2 \). Let \( \mathcal{A}t \) be the set of atoms ranged over by \( a, b \); \( A \) be the set of atom-variables ranged over by \( A, B \); \( S \) be the set of expression-variables ranged over by \( S, T \) standing for expressions; \( D \) be the set of context-variables ranged over by \( D \) standing for single hole-contexts; and \( P \) be the set of permutation-variables ranged over by \( P \) standing for finite permutations on \( \mathcal{A}t \), i.e. bijections \( \pi \) on \( \mathcal{A}t \) such that their support \( \text{supp}(\pi) = \{ a \in \mathcal{A}t \mid \pi(a) \neq a \} \) is a finite set.

The ground expressions are lambda-expressions extended by function symbols, where the lambda-variables are called atoms. Contexts in the ground language are expressions over a language extended with a symbol \( [·] \) the hole (occurring only once), where expressions can be plugged in. The language will be enriched by symbols for atoms, expressions, contexts, and permutations, where the latter are mappings that may change the names of atoms and are represented by lists of swappings \((a b)\).

**Definition 2.1** (The nominal language \( NL_{aASCP} \) with atom-variables, expression-variables,
context-variables, and permutation-variables). The syntax of $NL_{aASC}$ is defined by the grammar

$$
X \in A \mathcal{E} ::= a | A | \pi \cdot A
$$

$$
e \in \mathcal{E} ::= X | S | \pi \cdot S | (f \; e_1 \ldots e_{ar(f)}) | \lambda X.e | C[e]
$$

$$
C \in C ::= | | D | \pi \cdot D | (f \; e_1 \ldots e_n) | \lambda X.|.| | C_1[C_2]
$$

$$
\pi ::= \emptyset | (A_1 \; A_2) \cdot \pi | (A \; a) \cdot \pi | (a \; A) \cdot \pi | (a_1 \; a_2) \cdot \pi | P \cdot \pi | P^{-1} \cdot \pi
$$

with the categories $A \mathcal{E}$ of atom expressions, $\mathcal{E}$ of expressions, $C$ of contexts, and $\pi$ of permutations. Here $A, S, D,$ and $P$ is an atom-variable, expression-variable, context-variable, or permutation-variable, respectively.

Nested permutations are forbidden, e.g. swappings $(\pi_1 \cdot A_1 \; \pi_2 \cdot A_2)$ are excluded for simplicity of algorithms, and since their expressive power is already available using equations and constraints. We use positions (tree addresses) in expressions, where we ignore permutation expressions in the addressing scheme. Sublanguages of $NL_{aASC}$ are denoted by $NL_M$, where $M$ is a substring of $aASC$, and the grammar is restricted accordingly. The mainly used languages are $NL_a$ as ground language for the solutions, $NL_{aASC}$ as the expression language for the input, and $NL_{aASC}$ as the working language inside of the unification algorithm.

**Definition 2.2.** A substitution $\sigma : NL_{aASC} \rightarrow NL_{aASC}$ maps atom-variables to atom expressions, expression-variables to expressions, context-variables to contexts, permutation-variables to permutations. A ground substitution $\rho$ is a substitution $\rho : NL_{aASC} \rightarrow NL_a$. The mapping on atom-variables, expression-variables, context-variables and permutation-variables determines uniquely a mapping $\rho$ on all expressions of $NL_{aASC}$.

The semantics of the symbols is now explained, which will then justify the simplifications below. We use permutation application $\cdot$ as operator and syntactic symbol. Similarly, we use $^{-1}$ as a syntactic symbol in $P^{-1}$ and operator for inversion, and we abbreviate $\emptyset \cdot V$ by $V$ for a variable $V$.

**Definition 2.3 (Operations and Simplifications).** In all the languages we use the following operations and simplifications according to the semantics:

$$
(\pi_1 \cdot \pi_2)(e) \rightarrow (\pi_1, (\pi_2 \cdot e))
$$

$$
(\pi_1 \cdot \pi_2)^{-1} \rightarrow \pi_2^{-1} \cdot \pi_1^{-1}
$$

$$
\pi[:] \rightarrow [:]
$$

$$
\pi(f \; e_1 \ldots e_n) \rightarrow (f \; \pi \cdot e_1 \ldots \pi \cdot e_n)
$$

$$
\pi(\lambda X.e) \rightarrow \lambda \pi \cdot X.\pi \cdot e
$$

$$
\pi \cdot C[e] \rightarrow (\pi \cdot C)[\pi \cdot e]
$$

$$
(X_1 \; X_2)^{-1} \rightarrow (X_1 \; X_2)
$$

$$
(C_1 \; C_2)[e] \rightarrow C_1[C_2[e]]
$$

**Remark.** The simplifications permit standardizations in the various languages:

- In $NL_a$, all permutation operations can be simplified away.
- In the language $NL_{aS}$ permutations can be represented as list of swappings of length at most $|n - 1|$.
- In the language $NL_{aASC}$, the permutation operations only lead to suspensions of the form $\pi \cdot A, \pi \cdot S,$ and $\pi \cdot D$.
- In all languages, permutations can be represented as a composition of lists of swappings, permutation-variables $P$ and their inverses $P^{-1}$.
- Context expressions can be simplified such that context-variables only occur in the form $(\pi \cdot D)[e]$.

Let $\text{tops}(e)$ be the top symbol of $e$ after simplification of permutation applications, i.e. $\text{tops}(a) = \text{atom}$, $\text{tops}(\lambda X.e) = \lambda$, $\text{tops}(f \; e_1 \ldots e_n) = f$, $\text{tops}(\pi \cdot A) = A$, $\text{tops}(\pi \cdot S) = S$, and
For an expression $e$ or context $C$ in $NL_a$, we denote with $FA(e)$ or $FA(C)$, resp., the set of free atoms, and with $At(e)$ or $At(C)$, resp., the set of all atoms. The set of atoms that become bound in the hole of a context $C$, called the \textit{captured atoms} of $C$, is denoted as $CA(C)$.

In $NL_a$, $\alpha$-equivalence $\sim_{\alpha}$ is the closure by reflexivity and congruence and the rule $a \not\in FA(e') \land e \sim_{\alpha} (a \ b) \cdot e' \implies \lambda a.e \sim_{\alpha} \lambda b.e'$.

We also use a notion of $\alpha$-equivalence for contexts, defined as follows:

\begin{definition}[$\alpha$-equivalences on contexts in $NL_a$] $NL_a$-contexts $C_1$ and $C_2$ are $\alpha$-equivalent, written $C_1 \sim_\alpha C_2$, iff for all atoms $a$, $C_1[a] \sim_\alpha C_2[a]$ holds.

E.g., $\lambda a.[\cdot] \not\sim_\alpha \lambda b.[\cdot]$, $\lambda a.\lambda b.[\cdot] \sim_\alpha \lambda b.\lambda a.[\cdot]$, but $\lambda a.\lambda b.[\cdot] \not\sim_\alpha \lambda a.\lambda a.[\cdot]$. In Definition 2.4 it is sufficient for $C_1 \sim_\alpha C_2$, if $C_1[a] \sim_\alpha C_2[a]$ for all $a \in CA(C_1) \cup CA(C_2) \cup \{a'\}$, where $a'$ is a fresh atom. Note that $C_1 \sim_\alpha C_2$ and $e_1 \sim_\alpha e_2$ imply $C_1[e_1] \sim_\alpha C_2[e_2]$, but the reverse is wrong: $(f \ a \ \lambda a.a) \sim_\alpha (f \ a \ \lambda b.b)$, but $(f \ a \ \lambda a.[\cdot]) \not\sim_\alpha (f \ a \ \lambda b.[\cdot])$ and $a \not\sim_\alpha b$. We explain instantiation modulo $\alpha$ for correctly defining solvability under dvc-restrictions.
\end{definition}

\begin{definition}[Instantiation modulo $\alpha$] For testing solvability of equations, we assume that ground substitutions map into $NL_a/\sim_\alpha$. An equivalent method is that whenever a variable $S$ or $D$ is replaced by $\rho$, we use an $\alpha$-renamed copy of $Sp$ or $Dp$, respectively, where the renaming is done by fresh atoms that do not occur elsewhere (called instantiation modulo $\alpha$), and where comparison is done modulo $\sim_\alpha$.

The following definition explains free/bound variables and the satisfiability of dvc-constraints of expression in $NL_a/\sim_\alpha$ without using fresh variables.

\begin{definition} Let $e$ be a normalized $NL_a$ASCP-expression and $\rho$ be a ground substitution mapping into $NL_a/\sim_\alpha$, such that $ep$ is an $NL_a/\sim_\alpha$-expression. Then we define the bound atoms $BA(e, \rho)$, and satisfiability of the dvc of $(e, \rho)$ as follows, where the bound atoms introduced by $\rho$ are ignored.

\begin{enumerate}
    \item If $X$ is an atom $a$ or a suspension $\pi\cdot A$ where $A$ is an atom-variable then $BA(X, \rho) = \emptyset$, and the dvc is satisfied.
    \item $BA(\pi\cdot S, \rho) = \emptyset$, and the dvc is satisfied.
    \item $BA\bigl(f_{e_1} \ldots f_{e_n}, \rho\bigr) = \bigcup_{i=1}^n BA(e_i, \rho)$. The dvc is satisfied, if for all $i \neq j$, $BA(e_i, \rho) \cap (FA(e_j, \rho) \cup BA(e_j, \rho)) = \emptyset$ and for all $i$, the dvc holds for $(e_i, \rho)$.
    \item $BA(\lambda X.e, \rho) = BA(e, \rho) \cup \{X\rho\}$. The dvc is satisfied, if it is satisfied for $(e, \rho)$, and if $X \not\in BA(e, \rho)$.
    \item $BA\bigl((\pi\cdot D)[e], \rho\bigr) = BA(e, \rho) \cup ((\pi)\rho) \cdot (CA(D\rho))$. The dvc is satisfied, if it is satisfied for $D$, i.e. $CA(D\rho) \cap FA(D\rho) = \emptyset$ as well as $(BA(e, \rho) \cap ((\pi)\rho) \cdot (FA(D\rho)) \cup CA(D\rho))) = \emptyset$, and the dvc is satisfied for $(e, \rho)$.
\end{enumerate}

Note that $BA(e, \rho) \neq BA(ep)$, since for $e = \lambda a. S, \rho = \{A \mapsto a, S \mapsto \lambda b.a b\}$, we have $BA(ep) = \{a, b\}$, but $BA(e, \rho) = \{a\}$ (where we do not distinguish between an atom and the $\alpha$-equivalence class of an atom).

Nominal unification is connected with formulating and solving constraints. One form of constraints are freshness constraints:

\begin{definition}[Freshness-Constraints in $NL_a$ASCP] Freshness constraints in $NL_a$ASCP are of the form $a \# e$ and $A \# e$. The semantics of freshness constraints is as follows: For a ground substitution $\rho$, we say that

$\implies \rho$ satisfies $A \# e$ iff $\rho(A) \not\in FA(\rho(e))$;
\end{definition}
A set of freshness constraints is **satisfiable** iff there exists a ground substitution \( \rho \) in \( NL_{\alpha,ASCP} \) that satisfies all constraints. If \( \rho \) satisfies all constraints of a set of freshness constraints, then we say that \( \rho \) is a **solution** of the constraint set.

Another form of constraints is derived from the distinct variable convention.

**Definition 2.8 (dvc-Constraints).** The distinct variable condition (dvc) holds for an \( NL_{\alpha} \)-expression \( e \), if all bound atoms in \( e \) are distinct, and all free atoms in \( e \) are distinct from all bound atoms in \( e \).

A **dvc-constraint** is of the form dvc\( (e) \), where \( e \) is an expression. A ground substitution \( \rho \) satisfies dvc\( (e) \), iff the distinct variable condition holds for \( \rho(e) \) where \( \rho(e) \) is generated by using instantiation modulo \( \alpha \) (Def. 2.5). A dvc-constraint is **satisfiable** if there exists a satisfying ground substitution \( \rho \). If \( \rho \) satisfies all constraints of a set of dvc-constraints, then we say that \( \rho \) is a solution of the constraint set.

For example, \( f a \lambda b.(g a \lambda c.c) \) satisfies the dvc and \( f b \lambda b.b \) violates it. With \( \rho = \{ S \mapsto \lambda c.c \} \) we have \( f (\lambda a.S)(\lambda b.S) \rho = f (\lambda a.\lambda c_1.c_1)(\lambda b.\lambda c_2.c_2) \) and thus \( \rho \) satisfies dvc\( (f (\lambda a.S)(\lambda b.S)) \).

As another example, \( \rho' = \{ S \mapsto \lambda c.b \} \) violates dvc\( (f (\lambda a.S)(\lambda b.S)) \). Finally, note that the constraint dvc\( (f (\lambda a.S)(\lambda a.S)) \) is not satisfiable.

**Remark.** We will prove below in Proposition 3.8 that freshness constraints can be expressed as dvc-constraints if they occur in unification problems.

Although freshness constraints are redundant under the assumptions above, we still use them, since it is an important special case in nominal unification. Later we show, that dvc-constraints are a proper generalization of freshness constraints, dependent on the used language.

We now give an extended example of the use of constraints.

**Example 2.9.** A reduction rule of the corresponding calculus is let \( x = \lambda y.s \) in \( C[x] \rightarrow \) let \( x = \lambda y.s \) in \( C[\lambda y.s] \) where \( C \) is a context. (Note that we do not exactly represent the reduction rule from [2] here.) We represent the expressions as

\[
(\text{let } (\lambda A_x.D[A_x]) (\lambda A_y.S)) \text{ and } (\text{let } (\lambda A_x.D[\lambda A_y.S]) (\lambda A_y.S)).
\]

However, \( D \) is not permitted to capture the atom represented by \( A_y \), nor free atoms from \( S \), and \( S \) is not permitted to have free occurrences of \( A_x \). Both conditions can be captured by the constraint that instances of let \( (\lambda A_x.D[A_x]) (\lambda A_y.S) \) and let \( (\lambda A_x.D[\lambda A_y.S]) (\lambda A_y.S) \) have to satisfy the dvc. However, the latter violates the dvc in every case due to the two occurrences of the binder \( A_y \). Hence, we add a renaming to the rule and represent it as

\[
(\text{let } (\lambda A_x.D[A_x]) (\lambda A_y.S)) \rightarrow (\text{let } (\lambda A_x.D[(A_y A_z)\cdot A_y.S]) (\lambda A_y.S)) \text{ and } A_z \neq S,
\]

which is simplified to

\[
(\text{let } (\lambda A_x.D[A_x]) (\lambda A_y.S)) \rightarrow (\text{let } (\lambda x.D[\lambda A_z.(A_y A_z)\cdot S]) (\lambda A_y.S)) \text{ and } A_z \neq S.
\]

Now the dvc-constraints for both expressions makes sense and produces the correct conditions.

**Definition 2.10.** Let \( L \) be a sublanguage of \( NL_{\alpha,ASCP} \). A **nominal unification problem** in \( L \) is a pair \( (\Gamma, \nabla) \) where \( \Gamma \) is a finite set of equations \( e = e' \) with \( e, e' \in L \) and \( \nabla \) is a finite
set of freshness and $dvc$-constraints, where all expressions are in $L$. A ground substitution $\rho$ is a solution of $(\Gamma, \nabla)$ iff $\rho$ satisfies $\nabla$ and $e\circ\rho = e'$ for all $e \in \Gamma$.

A unifier for $(\Gamma, \nabla)$ is a pair $(\sigma, \nabla')$ in $L$, where $\sigma$ is a substitution and $\nabla'$ is a set of constraints, such that $\nabla'$ is satisfiable and for every substitution $\gamma$ such that $\sigma \circ \gamma$ is ground for $\Gamma, \nabla, \nabla'$:

$$(\sigma \circ \gamma) \text{ satisfies } \nabla' \implies (\sigma \circ \gamma) \text{ is a solution for } (\Gamma, \nabla)$$

For a nominal unification problem $(\Gamma, \nabla)$ in $L$, a set $M$ of unifiers is complete, iff for every solution $\rho$ of $(\Gamma, \nabla)$, there is a unifier $(\sigma, \nabla') \in M$ such that there is a ground substitution $\gamma$ with $A\sigma\gamma = \rho(A)$, $S\sigma\gamma \sim_\alpha \rho(S)$, $D\sigma\gamma \sim_\alpha \rho(D)$, and $P\sigma\gamma = \rho(P)$ for all atom-variables $A$, expression-variables $S$, context-variables $D$ and permutation-variables $P$ occurring in $(\Gamma, \nabla)$ (we say $(\sigma, \nabla')$ covers $\rho$). A unifier $(\sigma, \nabla')$ is a most general unifier of $(\Gamma, \nabla)$, iff $\{(\sigma, \nabla')\}$ is a complete set of unifiers for $(\Gamma, \nabla)$.

**Theorem 2.11** ([36, 6, 18, 17]). The nominal unification problem in $NL_{aS}$, with $\nabla$ consisting of freshness constraints only, is solvable in quadratic time and is unitary: For a solvable nominal unification problem $(\Gamma, \nabla)$, there exists a most general unifier of the form $(\sigma, \nabla')$ which can be computed in polynomial time.

In Theorem 6.1 we show that our unification algorithm solves the same problem where $dvc$-constraints are permitted, also in polynomial time.

**Definition 2.12.** An $ASD1$-unification problem is a set of $NL_{aASC}$-equations, where context variables occur at most once, all top-expressions in equations have a $dvc$-constraint, and the equations have to be solved w.r.t. $\alpha$-equivalence.

## 3 Preparations for $NL_{aASC}$-Unification

In this section we will analyze properties of contexts and expressions, where we will see that the use of $dvc$-constraints is of considerable help. This is a preparation for the unification rules for treating unification equations of the form $D_1[e_1] = D_2[e_2]$ decomposing expressions with context-variables, and it is a natural requirement for overlaps of (the instances of) rules and transformations.

**Lemma 3.1.** Let $e$ be an $NL_a$-expression. Then there is an expression $e'$ that satisfies the $dvc$ with $e \sim_\alpha e'$.

**Proof.** The argument is a simple bottom-up algorithm that renames all bound atoms by fresh ones.

**Lemma 3.2.** Let $e$ be an $NL_a$-expression that satisfies the $dvc$ and $\pi$ be a permutation. Then $\pi \circ e$ also satisfies the $dvc$.

**Proof.** This holds, since a permutation is a bijection on the atoms.

**Lemma 3.3.** Let $e_1, e_2$ be two expressions in $NL_a$ that satisfy the $dvc$ (separately). Then $e_1 \sim_\alpha e_2$ is equivalent to the condition that there exists a permutation $\pi$ with $e_1 = \pi \circ e_2$, where $\text{supp}(\pi) \subseteq (\mathcal{A}(e_1) \cup \mathcal{A}(e_2)) \setminus (\mathcal{F}(e_1) \cup \mathcal{F}(e_2))$.

**Proof.** If $e_1, e_2$ satisfy the $dvc$ and $e_1 = \pi \circ e_2$ where $\pi$ does not change free atoms of $e_1, e_2$, then clearly $e_1 \sim_\alpha e_2$. We prove the other direction of the claim by induction on the size.
We show below, that the latter rule is already the general one, provided the rule $\alpha$-equivalence:

$$
\begin{align*}
\frac{a \neq \lambda b \cdot s \cdot e}{\lambda a \cdot s, a \sim_{\alpha} (a \cdot b) \cdot s}
\end{align*}
$$

where $a$ may be equal to $b$ or different. Generalizing this for arbitrary contexts results in the next, slightly more complicated situation where $C_1 = \lambda a_1 \ldots \lambda a_n [\cdot]$, $C_2 = \lambda b_1 \ldots \lambda b_n [\cdot]$, and the rule

$$
\frac{CA(C_1) \neq CA(C_2) \exists \pi : (C_1 \sim_{\alpha} \pi \cdot C_2, s_1 \sim_{\alpha} \pi \cdot s_2)}{C_1[s_1] \sim_{\alpha} C_2[s_2]}
$$

where $\pi$ is a permutation with $\pi \cdot b_i = a_i$ for all $i$, $CA(C_1) = \{a_1, \ldots, a_n\}$, and $CA(C_2) = \{b_1, \ldots, b_n\}$. We assume that $a_i \neq a_j$, $b_i \neq b_j$ for $i \neq j$, but $a_i = b_j$ for some $i, j$ may hold. We show below, that the latter rule is already the general one, provided the DVC holds for $C_1[s_1]$ and $C_2[s_2]$.

We now analyze the decomposition of context applications $C[e]$ under the assumption that the DVC holds. Note that contexts like $\lambda a.\lambda a[\cdot]$ violate the DVC, and so are excluded. For an $NL_a$-context $C$, we denote with $CAO(C)$ the ordered tuple of the atoms in $CA(C)$, where the atom ordering is according to the nesting of active bindings: The outermost bound atom comes first. For example if $C = \lambda a.\lambda a.f (\lambda b.\lambda c.b) (\lambda b.\lambda b.[])$, then $CAO(C) = (a, b)$.

**Proposition 3.5.** Let $C_1, C_2$ be $NL_a$-contexts and $e_1, e_2$ be $NL_a$-expressions, such that $C_1$ and $C_2$ have identical hole positions, and such that $C_1[e_1]$ as well as $C_2[e_2]$ satisfy the DVC. Then the following are equivalent:

1. $C_1[e_1] \sim_{\alpha} C_2[e_2]$.
2. $\forall a \in CA(C_1): a \neq \lambda b \cdot s \cdot e$ and there is a permutation $\pi$ with $C_1 \sim_{\alpha} \pi \cdot C_2$ and $e_1 \sim_{\alpha} \pi \cdot e_2$, where $\pi$ does not change free atoms in $C_2[e_2]$, $\pi$ maps $CAO(C_2)$ to $CAO(C_1)$, and $supp(\pi) \subseteq CA(C_2) \cup CA(C_1)$.

**Example 3.6.** The DVC is required in Proposition 3.5: Let $C_1 = (a, \lambda a[\cdot])$ and $C_2 = (a, \lambda b[\cdot])$, which implies $C_1[a] = (a, \lambda a) \sim_{\alpha} (a, \lambda b, b) = C_2[b]$. The DVC is violated for the left expression. We see that there does not exist a (common) permutation $\pi$ with $C_1 \sim_{\alpha} \pi \cdot C_2$ and $e_1 \sim_{\alpha} \pi \cdot e_2$.

Note that exploiting the general decomposition property of context-variables above in a unification algorithm, even under strong restrictions, requires permutation-variables, and
also constraints of the form $CA(D) \# e$. There are investigations on nominal unification permitting variable permutations [7, 10], but an extension to context-variables is open. We will use further components in the constraint set that has $NL_{aASC}$ as its working language, which will refine the information.

**Definition 3.7 (Further Constraint Components).** Let $\rho$ be a ground substitution. The unification algorithm uses the following further constraint components:

- $A \neq e$, where $e$ is an atom expression. (short form of $A \# e$)
- $CA(D) \# e$, which is satisfied by $\rho$, if for all atoms $a \in CA(D_\rho)$: $a \# e_\rho$.
- $supp(\pi) \# e$, which is satisfied by $\rho$, if for all atoms $a \in supp((\pi)_\rho)$: $a \# e_\rho$.
- $supp(\pi) \subseteq CA(C_1) \cup CA(C_2)$ which is satisfied by $\rho$, if for all atoms $a \in supp((\pi)_\rho)$:
  
  - $a \in CA(C_1_\rho) \cup CA(C_2_\rho)$.
- $C \neq \emptyset$, which is satisfied by $\rho$, if $C_\rho$ is not the trivial context.

**Proposition 3.8.** In $NL$-languages containing expression-variables, freshness constraints can in linear time be encoded as $dvc$-constraints by translating $a \# e$ into $dvc((f(\lambda a.a) S))$, plus the equation $S = e$; and $A \# e$ into $dvc((f(\lambda A.A) S))$ plus the equation $S = e$ where $f$ is a binary function symbol, and in both cases, $S$ is a new expression-variable.

**Proof.** We consider the first case ($a \# e$). If the freshness constraint is satisfied by $\rho$, then $a$ does not occur free in $e_\rho$, hence the modulo-alpha-instantiation of $S$ by $\rho$ can be done without use of the atom $a$, and then the constraint is satisfied. To prove the converse, assume that the $dvc$-constraint is satisfied by $\rho$. Then $e_\rho$ cannot have a free atom $a$. Similar arguments hold for the other case. \(\blacklozenge\)

## 4 The Unification Algorithm NomUnifyASC for $NL_{aASC}$

The nominal unification problem in the language $NL_{aASC}$ without any restrictions seems to be too hard (at least we did not find an algorithm to solve it). One hint is that already context unification for first-order terms is a quite hard problem. Its solvability was open for decades and recently shown to be in $PSPACE$ [14]. That is why we restrict the input and allow only single occurrences of the same context-variable. A further complication are permutation-variables, since nominal unification with permutation-variables but without contexts, known as equivariant unification [7, 10], is known to be solvable in $EXPTIME$. If context-variables and permutations are combined, then it is unclear how to do constraint solving, since the (to be guessed) support of the permutations depends on the set of captured atoms occurring in the instance of context-variables, and it is unknown how to bound this number of atoms.

Thus, we describe a unification algorithm for ASD1-unification problems, where we permit additional freshness constraints.

Since double occurrences of context variables must be avoided during the execution of the algorithm, instantiations within the equations are not permitted: For example transitions using replacement starting with $S \equiv D[\ldots], S \equiv e_1, S \equiv e_2,\ldots$ may introduce two occurrences of $D$, since the result is $D[\ldots] \equiv e_1, D[\ldots] \equiv e_2,\ldots$. Thus we propose a Martelli-Montanari-style algorithm [21] that avoids instantiations within the unsolved equations.

\(\text{Fail}\) if \(\text{tops}(e_1)\) is \text{atom} or an atom-variable, or \(\text{tops}(e_1)\) is \(S\) and \(S\) occurs in \(e_2\); \(D \in \Delta\)

Figure 6 Failure Rules of NomUnifyASC

4.1 The Data Structures and Rules of NomUnifyASC

The state during unification is \((\Gamma, \nabla, \theta, \Delta)\) from \(NlaASC\), where \(\Gamma\) is a set of sets of expressions, so-called multi-equations, \(\nabla\) is a set of freshness and \(dvc\)-constraints and further constraints of Definition 3.7, \(\theta\) is a substitution in triangle-form\(^1\), represented as a set of components, and \(\Delta\) is a set of context-variables that are assumed to be nonempty. We explicitly write \(\Delta\) if needed.

Multi-equations \(M = \{e_1, \ldots, e_n\}\) will sometimes be written as \(e_1 \equiv e_2 \equiv \ldots \equiv e_n\). We will assume that the expressions in \(\Gamma\) are flattened, using iteratively the rule (flatten) in Fig. 1, i.e., in \((f \ e_1 \ldots e_n), \lambda\pi \cdot X \cdot e, \) and in \(D[e]\), the expressions \(e_i, e\) are of the form \(\pi \cdot X\), where \(X\) is an atom or expression-variable. For permutations, we assume that there is a compression scheme implementing sharing using an SLP [20] where a permutation is a composition (i.e., like a string) of the basic components \((a \ b), (A \ a), (a \ A), (A \ B), P, P^{-1}\), and the expansion of a representation may be exponentially long, and where the required operations on the permutations like composition and inverting can be done in polynomial time and space. However, to keep the presentation simple, we do not mention this compression and operations in the description of the unification rules.

\textbf{Definition 4.1 (NomUnifyASC).} The input of the non-deterministic algorithm NomUnifyASC is an ASD1-unification problem \((\Gamma, \nabla)\), where \(\Gamma\) is a set of equations and \(\nabla\) a set of \(dvc\)- and freshness constraints, both over \(NlaASC\). The internal data structure is a tuple \((\Gamma, \nabla, \theta, \Delta)\), over \(NlaASC\). The algorithm finishes either with Fail, or, if \(\Gamma\) is empty and no Failure rule applies, with a tuple \((\nabla', \theta, \Delta')\).

NomUnifyASC uses rules in rule sets: The rule (flatten) in Fig. 1 is applied until no longer applicable. Then the variable-replacement and usual decomposition rules in Fig. 2, the rules for decomposing multi-equations with expressions of the form \(D[\ldots]\), and with function symbols or \(\lambda\) as top symbol in Fig. 3, the decomposition rules for multi-equations of expressions \(D[\ldots]\) in Fig. 4, where the starred rules (DCPrem*) and (DCFork*) are not used directly; the rules for guessing context-variables as empty or nonempty in Fig. 5, and the failure rules in Fig. 6. Rules (CD1), (CD2) make one (parallel) decomposition step, where (CD1) first guesses a common first level of the hole positions of all \(D_i\). (DCPref) guesses that one context is a prefix of the others; (DCPrem*) guesses a (maximal) common prefix of

\(^1\) A substitution in triangle-form is a shared representation of a substitution, e.g., \(\{x \mapsto (f \ y \ z), y \mapsto a, z \mapsto \lambda b\}\), is the substitution \(\{x \mapsto f \ a \ (\lambda b), y \mapsto a, z \mapsto \lambda b\}\), i.e. the substitution itself is idempotent.
the contexts \(D_i\), and (DCFork*) guesses that \(D_i\) fork and the first level of the hole positions of \(D_i\).

The priorities of rule application are the sequence as above, i.e. the rules in Fig. 2, 3, 4, 5, 6. Within the rule sets, for rules in Figs. 2, 3, the priority is the sequence as given in the figures. For the rules in Figs. 4 and 5, within the rule sets the priority is the same. The failure rules can be applied at any time.

Example 4.2. For \(faS_2 S_1 \doteq f S_1 (\lambda a.S_3) S_3\) there is a substitution that equates the expressions. However, if there are dvc-constraints for the top expressions, which must be satisfied by unifiers, i.e. \([\text{dvc}(f S_1 S_2 S_1), \text{dvc}(f a (\lambda a.S_3) S_3)] \subseteq \nabla\), then these cannot be satisfied, since for example, the instantiation \(\rho(S_3) = a\) cannot be \(\alpha\)-renamed. Another example is \(f S S \doteq f (\lambda a.a) (\lambda b.b)\), which is solvable by \(\{S \mapsto a.a\}\): it does not lead to a dvc-violation, since it is treated as instantiation modulo \(\alpha\).

4.2 The Algorithm for Satisfiability of the Output

We define the non-deterministic algorithm that checks satisfiability of the output constraints, where we give the justification later in Section 5. The algorithm exploits the execution sequence of NomUnifyASC, since without this information a decision algorithm appears to be impossible since permutation-variables as well as context-variables appear in the constraint. I.e., we were unable to find an algorithm checking solvability of arbitrary constraints permitted by the syntax, i.e. with context-variables and permutation-variables. Thus we have to use the knowledge on the execution trace of the algorithm in order to decide satisfiability of the final constraints.

Definition 4.3. The algorithm NomFreshASC operates on the output \((\nabla, \theta, \Delta)\) of NomUnifyASC and uses the set of all atoms and atom-variables occurring in the execution sequence \(H\) leading to this output, and the number \(d\) of context-variables in the input. It performs the following steps:

(I) Iteratively guess the solution of atom-variables, i.e. for an atom-variable \(A\) guess that \(A\) is mapped by the solution to an already used atom in \(H\), or to a fresh one, and replace the atom-variable \(A\) accordingly in \(H\). In the next iteration the fresh atom is among the used ones. Let \(H'\) be the adjusted execution sequence. Note that the exact names of fresh atoms are irrelevant. Thus there is only a linear number (w.r.t. the number of used atoms) of possibilities for every atom-variable. Let \(M_A\) be the set of all atoms in the execution sequence \(H'\).

(II) Replace every expression-variable \(S\) that occurs in \(H'\) and that is not instantiated by \(\theta\), by a constant \(c\) from the signature.

(III) Construct \(M_\infty\) as a set of \(|M_A| \cdot (d!)^2\) atoms by extending the set \(M_A\) by further fresh atoms, where \(d\) is the number of context-variables in \(\Gamma\). Guess for every context-variable \(D\) that occurs in \(\Gamma, \nabla, \theta\) and that is not instantiated by \(\theta\), the ordered set of captured atoms from the given set of atoms.

(Note that the number of potentially generated atoms is at most exponential, see Lemma 5.7.)

(IV) Guess the permutation-variables as bijections on the set \(M_\infty\).

(V) Test the freshness constraints, equality, disequality, extended freshness constraints, and non-emptiness constraints, which are now immediately computable. To test whether the \(\theta\) violates the dvc in \(\Gamma\), use dynamic programming to compute the sets \(FA, BA\) for every expression- and context-variable, and \(CA(D)\) for the context-variables \(D\) that are not instantiated by \(\theta\). Then test the dvc-property, which is possible in polynomial time.
Properties of $\text{NomUnifyASC}$ and $\text{NomFreshASC}$

Let $\text{maxArity}$ be the maximal arity of function symbols in the signature.

Lemma 5.1. The number of occurrences of any context-variable in $\Gamma$ in every state of $\text{NomUnifyASC}$ is at most 1.

An example which shows that implicitly requiring the $dvc$ is not stable, in contrast to requiring explicit $dvc$-constraints, is $\{S_1 = f (\lambda a.a) (\lambda a.a)\}$. It does not satisfy the $dvc$, but after applying (flatten) to position 1 of the right hand side, we obtain $\{S_1 = (f S (\lambda a.a)), S = \lambda a.a\}$ which has the solution $\{S \mapsto \lambda a.a, S \mapsto (f (\lambda' a') (\lambda a.a))\}$. If the initial set $\nabla$ contains $\text{dvc}(f (\lambda a.a) (\lambda a.a))$, then there is no solution before and after flattening, since (flatten) cannot be applied to expressions within $\nabla$.

Lemma 5.2. If the input is $(\Gamma, \nabla)$, then the application of (flatten) to a subexpression of $e$ of the equations $\Gamma$ does not change the set of solutions.

Proof. Obvious, since $\sim_{\alpha}$ is a congruence.

Proposition 5.3. For an $\text{NL}_{aASC}$-input $\Gamma, \nabla$, the non-deterministic algorithm $\text{NomUnifyASC}$ terminates after a polynomial number of steps.

Proof. First we define the measure:

- $\mu_1 := \mu_{1,1} + 2 \cdot \text{maxArity} \cdot \mu_{1,2}$, where $\mu_{1,1}$ is the number of expressions in $\Gamma$, and $\mu_{1,2}$ is the number of occurrences of function symbols and $\lambda$-s in $\Gamma$;
- $\mu_2$ is $\mu_{1,1}$ minus the number of multi-equations. Note that $0 \leq \mu_2 \leq \mu_1$;
- $\mu_3$ is the pair consisting of the number of occurrences of context-variables $D$ in $\Gamma$ and the number of context-variables $D$ occurring in $\Gamma$ which are not in $\Delta$;
- $\mu_4$ is the number of occurrences of expressions $\lambda X$, where $X$ is of the forms $\emptyset a, \pi a$, or $\pi A$ and where $\pi$ is nontrivial.

The following table lists the relation between $\Gamma$ before and after the application of the rule or subalgorithm.

<table>

It can be verified for (MEi), (FP), (Df), (Abstr), (Dlam), and (CD0) by a simple check. It is correct for (CD1) and (CD2), since the expression $f e_1 \ldots e_m$ is removed, which counts $2^{\text{maxArity}}$. (DCPref) removes one occurrence of a context-variable. (DCFork) splits the context-directions, and first introduces expression-variables $S_i$ which are then removed. Hence the number of expressions in multi-equations is the same, but there are more multi-equations. For (DCPRem), it suffices to check (DCFork). The measure $\mu_3$ is not increased by any rule, and $\mu_2 \leq \mu_1$, and $\mu_4 \leq \mu_1$, hence the number of executions of rules is polynomial. Since there are multiple sub-steps, we have to argue that a single rule application can be done in polynomial time. The number of steps within the rules is polynomial due to the strict decrease w.r.t. the orderings. We add a (standard, SLP) compression scheme using sharing, which implies that all operations on the permutations like flattening, inverting and composition can be done in polynomial time and space.

The assumptions on the $dvc$-constraints ensure that for every solution $\rho$ and input expression $e$ in $\Gamma$, the instance $e\rho$ satisfies the distinct variable condition.
Lemma 5.4. If all top expressions of the initial set of equations $\Gamma$ are restricted by the DVC, then this also holds for all top-expressions in the sequence of rule executions of the algorithm NomUnifyASC.

Proposition 5.5. Inspecting the details of all rules of NomUnifyASC shows soundness: The solutions of the final data structure are also solutions of the input. The following rules of the algorithm NomUnifyASC do not lose any solutions, i.e., for every solution $\rho$ of the data structure $Q$ before application, there is a solution $\rho'$ of the output data structure $Q'$, such that $\rho(X) \sim_\alpha \rho'(X)$ for all atom-, expression-, context- and permutation-variables $X$ occurring in $Q$: These are rules in Fig. 2, and rules (CD0), (CD2) from Fig. 3. In addition the failures rules do not lose any solutions, since they are only applicable, if there are no solutions.

Proposition 5.6. Assume that for all top-expressions $e$ in the input $\Gamma$, there is a constraint $\text{dvc}(e)$ in $\nabla$. Then the algorithm NomUnifyASC is complete: If $\rho$ is a solution of the intermediate data structure $Q$, $\Gamma$ is not empty and no Failure rule applies, then there is a possible rule application, such that there is solution $\rho'$ of the output $Q'$, and $\rho(X) \sim \rho'(X)$ for all atom-, expression-, context- and permutation-variables $X$ occurring in $Q$.

We now consider the correctness and complexity of NomFreshASC.

Lemma 5.7. Let $H$ be an execution of NomUnifyASC starting with $S_0 := (\Gamma_0, \nabla_0, \theta_0, \Delta_0)$ where $\Gamma_0 = \Gamma$, context variables occur at most once, and $\theta_0, \Delta_0$ are trivial or empty. Let the sequence $H$ end with $S_{\text{out}} = (\emptyset, \nabla_{\text{out}}, \theta_{\text{out}}, \Delta_{\text{out}})$, and let $\rho$ be a solution of the input as well as of the output $S_{\text{out}}$. Then there is also a solution $\rho'$ that uses only a set of atom $\text{VA}_\infty$ with $|\text{VA}_\infty| \leq |\text{VA}| + \lfloor((d!)^2)^2\rfloor$, where the visible set $\text{VA}$ of atoms $\text{VA} = \{a | a \text{ occurs in } H\} \cup \{Ap | A \text{ occurs in } H\}$, and where $d$ is the number of context-variables in $\Gamma$.

Proposition 5.8. Let $(\nabla_{\text{out}}, \theta_{\text{out}}, \Delta_{\text{out}})$ be the output of NomUnifyASC for input $(\Gamma, \nabla)$. The algorithm NomFreshASC decides satisfiability of the output in NEXPTIME in the size of the input, where the main components are $|\Gamma, \nabla|\ast((d!)^2)$, where $d$ is the number of context-variables in $\Gamma$. For a fixed upper bound on the number of context-variables, satisfiability can be checked in NP time.

Proof. This mainly follows from Lemma 5.7.

Remark. There is a complexity jump between freshness constraints and DVC-constraints in the language NL$_{aSC}$, since satisfiability of freshness constraints in NL$_{aSC}$ is in PTIME whereas satisfiability of DVC-constraints in NL$_{aSC}$ is NP-hard.

Combining Propositions 5.6, 5.3, and 5.8 shows:

Theorem 5.9. For $\Gamma, \nabla$ as input the algorithm NomUnifyASC terminates and is sound and complete. The computation of some output $(\nabla', \theta', \Delta')$ can be done in NP-time, and the collecting version of the algorithm produces at most exponentially many outputs $(\nabla', \theta', \Delta')$. Decidability of solvability of output constraints, and hence of the input, is in NEXPTIME, and if the number of context-variables is fixed, then in NP time.

Theorem 5.10. Solvability of ASD1-unification problems is in NEXPTIME.

6 Specializations, Applications and Examples

We consider nominal unification in NL$_aS$ with freshness and DVC-constraints extending the result of [36] (see Theorem 2.11) by allowing DVC-constraints and by restricting NomUnifyASC.
The nominal unification problem in NL\textsubscript{AS} where freshness- and dvc-constraints are permitted in $\nabla$ is solvable in polynomial time. Moreover, for solvable $(\Gamma, \nabla')$, there exists a most general unifier of the form $(\nabla', \theta)$ which can be computed in polynomial time, i.e., the problem class is unitary.

The application of NomUnifyASC to NL\textsubscript{AS} also yields at most one most general unifier, however, the complexity to check solvability is increased, since already the solvability of freshness constraints in NL\textsubscript{AS} is NP-hard [32].

We now consider applications and examples. Most reduction and transformation rules in the application domain of functional programming languages require freshness and/or dvc-constraints to exclude invalid instances of the rules.

\begin{example}
We provide rules that can be described by our language. The rule app $(\lambda A \cdot S') \rightarrow \text{let } A = S' \text{ in } S$ is a sharing-variant of $\beta$-reduction. It needs the constraint dvc(app $(\lambda A \cdot S')$) if let is recursive, to ensure that for the instances, there are no free occurrence of $A \rho$ in $S' \rho$.

The rule let $A = S$ in $D[A]$ $\rightarrow$ let $A = S$ in $D[S]$ copies a single expression to some position of the bound atom. The expression is represented by the expression-variable $S$, and the target position by the context-variable $D$. The constraint dvc(let $A = S$ in $D[A]$) prevents capturing in instances, s.t. $A \rho$ is not captured by $D \rho$. The constraint dvc(let $A = S$ in $D[S]$) prevents that $D \rho$ captures atoms that are free in $Sp$. Since instances $Sp$ are $\alpha$-renamed (let $A = S$ in $D[S]$)$\rho$, these constraints suffice.
\end{example}

\begin{example}
We describe an exemplary unification problem that occurs in correctness proofs of program transformations. A reduction rule in the let-calculus of [2] is let $A_y := (\lambda A_z \cdot S_y \rho \text{ in } S_z\rho) \in S_r$ $\rightarrow$ let $A_y := S_y \rho \text{ in } S_z \rho$ with dvc-constraint dvc(let $A_y := (\lambda A_z \cdot S_y \rho \text{ in } S_z\rho)$) that prevents the occurrence of $A_y$ as free atom in $S_r$, and thus an unwanted capture in the right hand side. To check whether there is a (preferably nontrivial) overlap of the left hand side of the rule with itself (as a transformation) we form the unification equation let $A_z := (\lambda A_y \cdot S_y \mu \text{ in } S_z) \in S_r \equiv D[\text{let } A'_y := (\lambda A'\nu \cdot S'_y \mu \text{ in } S'_z) \in S'_r]$ where the context-variable $D$ is intended as a representation of the reduction strategy\footnote{In general, the reduction strategy has to be represented by context classes as in [31].}.

For correct application, the constraints dvc(let $A_y := (\lambda A_z \cdot S_y \mu \text{ in } S_z) \in S_r$) and dvc($D[\text{let } A'_y := (\lambda A'\nu \cdot S'_y \mu \text{ in } S'_z) \in S'_r]$) are required. We omit the case that $D \mapsto []$ and analyze the instantiation $D \mapsto ((\text{let } A_z := D_1 \text{ in } S_z))$. We obtain the equation let $A_y := S_y \mu \text{ in } S_z \equiv D_1[\text{let } A'_y := (\lambda A'\nu \cdot S'_y \mu \text{ in } S'_z) \in S'_r]$. Guessing $D_1 \mapsto []$ results in let $A_y := S_y \mu \text{ in } S_z \equiv A'_y := (\lambda A'\nu \cdot S'_y \mu \text{ in } S'_z) \in S'_r$. Guessing $A_y \mapsto A'_y$, we obtain as solution $S_y \equiv (\lambda A'_y \cdot S'_y \mu \text{ in } S'_z), S_z \equiv S'_r$. If we alternatively guess $A_y \neq A'_y$, we obtain as solution $S_y \equiv (\lambda A'_y \cdot S'_y \mu \text{ in } S'_z) \in S'_r$ and $S_z \equiv (A_y A'_y \cdot S'_y \mu \text{ in } S'_z) \in S'_r$ together with the constraints $A_y \# S'_r$.
\end{example}

\begin{example}
An example with two occurrences of an $S$-variable is the copy rule [2, 23, 33] let $A_z := \lambda A_y \cdot S \text{ in } D[A_z] \rightarrow$ let $A_z := \lambda A_y \cdot S \text{ in } D[\lambda A_z \cdot (A_y A_z) - S]$ with dvc(let $A_z := \lambda A_y \cdot S \text{ in } D[A_z]$) and dvc(let $A_z := \lambda A_y \cdot S \text{ in } D[\lambda A_z \cdot (A_y A_z) - S]$) as constraints, which imply that $A_y \rho$ is not captured in $D \rho$, and that $A_z \# S$ is valid. The diagram proof technique [33] also needs to overlap right-hand sides of program transformations with left hand sides of the copy rule. We overlap the right hand side and the left hand side of the copy rule at the top position. The problem $(\Gamma, \nabla)$ in NL\textsubscript{ASC} with $\Gamma = \{D_0[\text{let } A_{z,1} := \lambda A_{y,1} \cdot S_1 \text{ in } D_1[\lambda A_{z,1} \cdot (A_{y,1} A_{z,1}) - S_1]\}$
We described and analyzed a nominal unification algorithm for a language with higher-order expressions and variables for atoms, expressions and contexts. The formalism like adding grammars for context classes. Knowledge may be built into the unification mechanism which would require an extension of the nominal unification mechanism like adding grammars for context classes.

7 Conclusion and Further Work

We described and analyzed a nominal unification algorithm for a language with higher-order expressions and variables for atoms, expressions and contexts.

Further work is to extend and adapt the unification and constraint solution method to more constructs of higher-order languages, like a recursive-let, or context-classes.

A Detailed Proofs

A.1 Multi-Contexts

Definition A.1. We introduce \( n \)-contexts for some \( n \geq 1 \) (also called multi-contexts) in \( \text{NL}_a \). These are expressions of \( \text{NL}_a \) extended by constants (holes) \([\cdot], i = 1, \ldots, n\), where every hole occurs at most once. For \( n \geq 1 \) and two \( n \)-contexts \( C_1, C_2 \) the relation \( C_1 \sim_{\alpha} C_2 \) holds, iff for all \( n \)-tuples \( a_1, \ldots, a_n \) of (perhaps equal) atoms \( a_i \), it holds that \( C_1[a_1, \ldots, a_n] \sim_{\alpha} C_2[a_1, \ldots, a_n] \) as expressions, which is a generalization from contexts (Definition 2.4) to multi-contexts.

The following lemma helps in the completeness proof of rule (DCFork).

Lemma A.2. Let \( n \geq 1 \), \( C_1, C_2 \) be \( \text{NL}_a \)-contexts, and \( e_{1,i}, e_{2,i}, i = 1, \ldots, n \) be \( \text{NL}_a \)-expressions, such that the corresponding hole positions of \( C_1 \) and \( C_2 \) are identical, and such that \( C_1[e_{1,1}, \ldots, e_{1,n}] \text{ and } C_2[e_{2,1}, \ldots, e_{2,n}] \) satisfy the dvc. Then \( C_1[e_{1,1}, \ldots, e_{1,n}] \sim_{\alpha} C_2[e_{2,1}, \ldots, e_{2,n}] \) iff the following holds:

\[ \text{CAO}(C_1) \neq \text{CAO}(C_2) \text{ and there is a permutation } \pi \text{ that does not change free atoms in } C_2[e_{2,1}, \ldots, e_{2,n}] \text{ with } C_1 \sim_{\alpha} \pi \cdot C_2 \text{ and } e_{1,i} \sim_{\alpha} \pi \cdot e_{2,i} \text{ for all } i, \pi \text{ maps CAO}(C_2) \text{ to CAO}(C_1), \text{ and } \text{supp}(\pi) \subseteq \text{CAO}(C_1) \cup \text{CAO}(C_2). \]

A.2 Properties of DVC-Constraints

Lemma 3.3. Let \( e_1, e_2 \) be two expressions in \( \text{NL}_a \) that satisfy the dvc (separately). Then \( e_1 \sim_{\alpha} e_2 \) is equivalent to the condition that there exists a permutation \( \pi \) with \( e_1 = \pi \cdot e_2 \), where \( \text{supp}(\pi) \subseteq (\text{At}(e_1) \cup \text{At}(e_2)) \setminus (\text{FA}(e_1) \cup \text{FA}(e_2)) \).

Proof. If \( e_1, e_2 \) satisfy the dvc and \( e_1 = \pi \cdot e_2 \) where \( \pi \) does not change free atoms of \( e_1, e_2 \), then clearly \( e_1 \sim_{\alpha} e_2 \). We prove the other direction of the claim by induction on the size. For constants and atoms, this is trivial, since \( \pi \) does not change free atoms. If \( e_1 = \lambda a.e_1' \), and \( e_2 = \lambda a.e_2' \), then \( e_1' \sim_{\alpha} e_2' \), hence \( e_1' = \pi \cdot e_2' \), for a (minimal) permutation \( \pi \). Hence \( e_1 = \pi \cdot e_2 \). Let \( e_1 = \lambda \cdot e_1 \), and \( e_2 = \lambda b.e_2 \), with \( a \neq b \). Then \( a \neq e_2 \), \( a \neq e_2' \), and \( e_1' \sim_{\alpha} (a \cdot b) \cdot e_2' \). The expressions \( e_1' \) and \( (a \cdot b) \cdot e_2' \) satisfy the dvc, by induction hypothesis, \( e_1' = \pi' \cdot (a \cdot b) \cdot e_2' \), for a permutation \( \pi' \) where \( \pi'(a) = a \). Let \( \pi \) be the permutation \( \pi' \cdot (a \cdot b) \). Then \( \pi'(a \cdot b) \cdot b = a \). Hence \( \pi \cdot e_2 = e_1 \). If \( e_1 = f e_{1,1} \ldots e_{1,n} \), and \( e_2 = f e_{2,1} \ldots e_{2,n} \), then by induction there are permutations \( \pi_i \) such that \( \pi_i \cdot e_{2,i} = e_{1,i} \) for all \( i \). Since the permutations can be chosen minimal and are only determined by the binders, and since the dvc is assumed, the permutations are disjoint. Thus we can compose (i.e. union) the permutations, and obtain \( \pi = \pi_1 \ldots \pi_n \) as the required permutation.

A.3 Decomposition of Context-Applications

Proposition 3.5. Let \( C_1, C_2 \) be \( \text{NL}_a \)-contexts and \( e_1, e_2 \) be \( \text{NL}_a \)-expressions, such that \( C_1 \) and \( C_2 \) have identical hole positions, and such that \( C_1[e_1] \) as well as \( C_2[e_2] \) satisfy the dvc. Then the following are equivalent:

1. \( C_1[e_1] \sim_{\alpha} C_2[e_2] \).
2. \( \forall a \in \text{CAO}(C_1) : a \neq C_2[e_2] \text{ and there is a permutation } \pi \text{ with } C_1 \sim_{\alpha} \pi \cdot C_2 \text{ and } e_1 \sim_{\alpha} \pi \cdot e_2, \text{ where } \pi \text{ does not change free atoms in } C_2[e_2], \pi \text{ maps } \text{CAO}(C_2) \text{ to } \text{CAO}(C_1), \text{ and } \text{supp}(\pi) \subseteq \text{CAO}(C_2) \cup \text{CAO}(C_1) \).

Proof. We show “ \( \Rightarrow \) ” by induction on the length of the hole path of \( C_1 \).
If the length is 0, then the claim is trivial.

If $C_1 = f \ e_1 \ldots \ e_n$ then $C_2 = f \ e'_1 \ldots e'_n$. The capture condition holds, since

$$\text{CA}(C_i) = \text{CA}(C_i).$$

The assumption and the congruence property of $\sim_\alpha$ imply $e_i \sim_\alpha e'_i$ for all $i \neq k$. By the induction hypothesis there is a permutation $\pi_k$ satisfying the theorem, which is the required permutation.

If $C_1 = \lambda a.C'_1$ and $C_2 = \lambda a.C'_2$, then the capture condition holds, $C'_1[e_1]$ and $C'_2[e_2]$ are $\alpha$-equivalent, and we can apply the induction hypothesis.

If $C_1 = \lambda a.C'_1$ and $C_2 = \lambda b.C'_2$, then $a \# C'_2[e_2]$, and $C'_1[e_1] \sim_\alpha (a \ b) \cdot C'_2[e_2]$. The DVC also holds for $(a \ b) \cdot C'_2$, hence we can apply the induction hypothesis, and obtain

$$C'_1 \sim_\alpha \pi'(a \ b) \cdot C'_2,$$

and $e_1 \sim_\alpha \pi'(a \ b) \cdot e_2$, and $\forall c \in \text{CA}(C'_2): c \# (a \ b) \cdot C'_2[e_2]$. The equation $c = a$ is not possible, since $C_1[\cdot]$ satisfies the DVC; $c = b$ may be possible, but since $a \# C'_2[e_2]$, and due to the application of $(a \ b)$ there are no free occurrences of $b$ in $(a \ b) \cdot C'_2[e_2]$. This implies $\forall c \in \text{CA}(C_1): c \# C_2[e_2]$. The application $\pi'(a \ b) \cdot b$ results in $a$, since $\pi'$ does not change $a$. Hence the required permutation is $\pi' = \pi'(a \ b)$.

The reverse is easy: if there are two expressions $e_1 \sim_\alpha e_2$, $C_1[e_1], C_2[e_2]$ satisfy the DVC, and there is a permutation $\pi$ that does not change free atoms in $e_2$, and $C_1 \sim_\alpha \pi \cdot C_2$, then $C_1[e_1] \sim_\alpha \pi \cdot C_2[e_2]$. ▶

A.4 Completeness of NomUnifyASC

Proposition 5.6. Assume that for all top-expressions $e$ in the input $\Gamma$, there is a constraint $\text{DVC}(e)$ in $\triangle$. Then the algorithm NomUnifyASC is complete: If $\rho$ is a solution of the intermediate data structure $Q$, $\Gamma$ is not empty and no Failure rule applies, then there is a possible rule application, such that there is solution $\rho'$ of the resulting data structure $Q'$, and $\rho(X) \sim \rho'(X)$ for all atom-, expression-, context- and permutation-variables $X$ occurring in $Q$.

Proof. Let $\rho$ be a solution of the current state. We scan the cases:

1. We can assume that all multi-equations have at least two expressions since otherwise rule (ME1) is applicable.
2. We can also assume that all context-variables that occur in $\Gamma$ are contained in $\Delta$, by applying either (CD0), or one of the rules (GuessDEmpty) or (GuessDNonEmpty), where the choice is directed by the solution.
3. If there is a multi-equation that has only context-variables as top symbols, then one of the rules from Fig. 4 is applicable, depending on the solution $\rho$, and there is a solution $\rho'$ of the output that extends $\rho$. The condition that top-expressions in the input satisfy the DVC and that the input are ASD1-unification problems is necessary for the application of Proposition 3.5.
4. If there is a multi-equation such that all but one expression have context-variables as top symbols, then there are several possibilities: Since $D \in \Delta$ for all $D$, one of the rules from Fig. 3 is applicable, since either the context-variables' instances have a common prefix or not. Proposition 3.5 and the knowledge on permutations show that the execution of the rules is possible. In any case, there will be a solution $\rho'$ after the application that is an extension of $\rho$ (on the variables of $Q$).
5. For the other cases there are at least two expressions in the multi-equation, which do not have a context-variable as top-symbol. The failure rules are not applicable, since otherwise, there is no solution. If the top symbols of two expressions are $\lambda$, or function symbols, then rules (Df), (Abstr) or (Dlam) can be applied and there is a solution $\rho'$.
extending $\rho$ after the application. If there are two expressions of the form $\pi \cdot X$, where $X$ is an atom or expression-variable, then $(ME3)$, $(ME4a)$, $(ME4b)$, or $(ME5)$ is applicable, and there is a solution $\rho'$ extending $\rho$ after the application. Similar for the case where $\text{tops}(\cdot)$ yields atom twice. If one expression is of the form $\pi \cdot X$, and the other is not of this form, then we apply $(ME5)$ if this is possible.

6. The final case is that for all equations, the equation pattern permits only applications of rule $(ME5)$, all multi-equations have only two expressions, but the conditions on non-containment of $S$ in rule $(ME5)$ prevent this. Defining a quasi-ordering on the expression-variables generated by the containment ordering over equations shows that there are no finite instance-expressions for some expression-variable, which is impossible, since we have assumed that there are solutions. Indeed in this case a failure rule would apply. ▷

### A.5 Satisfiability of Constraints of NomUnifyASC

- **Lemma 5.7.** Let $H$ be a sequence of executions of NomUnifyASC starting with $S_0 := (\Gamma_0, \nabla_0, \theta_0, \Delta_0)$ where $\Gamma_0 = \Gamma$, the condition on the input are as stated in Definition 4.5, and $\theta_0, \Delta_0$ are trivial or empty. Let the sequence $H$ end with $S_{out} = (\emptyset, \nabla_{out}, \theta_{out}, \Delta_{out})$, and let $\rho$ be a solution of the input as well as of the output $S_{out}$. Then there is also a solution $\rho'$ that uses only a set of atom $VA_{\infty}$ with $|VA_{\infty}| \leq |VA| + ((|d|)^2)$, where the visible set $VA$ of atoms $VA = \{a \mid a \text{ occurs in } H\} \cup \{A\rho \mid A \text{ occurs in } H\}$, and where $d$ is the number of context-variables in $\Gamma$.

**Proof.** We show a stronger claim by induction on the steps of the execution: Let $D_F$ and $D_P$ be the set of context-variables $D_1$ in the applications of $(DCPref)$ in $H$ and $D_{1,0}$ in the application of $(DCPRem)$ in $H$, and $P_i, i = 2, \ldots, n$ in the applications of $(DCPref)$ and $(DCPrem)$, resp. Let us call these the focused context-variables and the focused permutation-variables in the respective rule applications. These are the set of context-variables that are moved to the codomain of $\theta$. The permutation-variables are exactly all the generated ones in $H$. Let $VA = \{a \mid a \text{ occurs in } H\} \cup \{A\rho \mid A \text{ occurs in } H\}$. Then the size of $VA$ is polynomial, since the execution sequence $H$ can be generated in polynomial time according to Proposition 5.3. The claim is: there is a solution $\rho'$ that uses only the set $VA_{\infty}$ of atoms, where $VA_0 = VA$, and $VA_i$ is constructed below, such that $|VA_{i+1}| \leq |VA_i| + d^2$, where $d$ is the number of context-variables in the input, and where $|VA_{i+1}| > |VA_i|$ only if rule $(DCPref)$ or $(DCPrem)$ was executed. The construction implies $VA_i \subseteq VA_{i+1}$. The final $VA_{\infty}$ is defined as the final $VA_i$.

We define the construction: Let $i$ be an index in $H$ and $S_i = (\Gamma_i, \nabla_i, \theta_i, \Delta_i)$ be a state in $H$ with set $VA_i$, such that the next step is $(DCPref)$ or $(DCPrem)$ leading to $S_{i+1}$. Let us assume that it is the first occasion in $H$ such that a focused context-variable or permutation-variable that is in the focus of a rule application $(DCPref)$ or $(DCPrem)$, uses an atom $a'$ in its instances under $\rho$, where $a' \notin VA_i$. Then the following changes are made to the solution $\rho$, resulting in $\rho'$ and a modified execution sequence $H'$.

- First consider the modification concerning the rule $(DCPref)$:
  - Let us consider the instances $(\text{CAO}(\pi_1; D_1)\rho), \ (\text{CAO}(\pi_2; D_{2,1})\rho), \ldots, (\text{CAO}(\pi_n; D_{n,1})\rho)$, (same notation as in the rule application). We can assume that $(\pi_1; D_1)\rho, \ \text{CAO}(\pi_2; D_{2,1})\rho, \ldots, \ \text{CAO}(\pi_n; D_{n,1})\rho$ only consist of $\lambda a_{k,1}, \ldots, a_{k,m}[,\cdot]$ where $m = |\text{CAO}(\pi_1; D_1)|$, by modifying the solution $\rho$, which is without effect on the further execution of the algorithm NomUnifyASC and
solvability. We show that the number of binders can be bounded: Luckily, we can also eliminate the binder at position \( j \), if \( a_{k,j} \) is not in \( V\alpha_i \) for all \( k \): eliminate the binder \( j \) in every context above, then modify the instantiation of the permutation-variables \( P_k \) such that these map exactly \( (\pi_i \cdot D_{1,1}) \rho \) to \( CAO(\pi_i \cdot D_j) \) for \( k \geq 2 \), which is justified by Proposition 3.5. Hence \( P_k \) does not need any extra fresh atoms in its support. Using the thus modified \( \rho \), we replace all atoms (as expressions) by the constant \( c \) at the following positions: If the atom at this position in the instance \( e_i \rho \) is an atom \( a_{k,j} \) for some \( k \).

- Since binders cannot be repeated, an upper bound on the maximal number of binders for a single context-variable is \( |V_i| \ast d' \), where \( d' \) is the number of context-variables in \( \Gamma_i \). The number of all used atoms in the instances is at most \( |V_i| \ast d' \ast d' \).

- Let \( \rho' \) be \( \rho \) after these modifications. The ground substitution \( \rho' \) is a solution of the state \( S_{i+1} \), and such that the same execution still leads to a final state that covers \( \rho' \). There is no effect on the execution of the rules of the algorithm, since the changes are only in the solution.

- Now consider the modification for the rule (DCPrem). It is similar to the previous case, but we detail it, since the names of variables are different.

- Consider the instances \( (CAO(\pi_1 \cdot D_{1,0}) \rho), \ldots, (CAO(\pi_m \cdot D_{n,0}) \rho) \). We can assume that \( (\pi_k \cdot D_{k,0}) \rho \) only consist of \( \lambda a_{k,1}, \ldots, a_{k,m}[\cdot] \) where \( m = |CAO(D_{1,0})| \), by modifying the solution \( \rho \), which is without effect on the execution of the algorithm NomUnifyASC and solvability. We can also eliminate the binder at position \( j \), if \( a_{k,j} \) is not in \( V\alpha_i \) for all \( k \), as follows: eliminate the binder \( j \) in every \( (\pi_k \cdot D_{k,0}) \rho \), then modify the instantiation of the permutation-variables \( P_k \) such that these map exactly \( CAO(D_{k,0}) \) to \( CAO(D_{1,0}) \) for \( k \geq 2 \). Using the thus modified \( \rho \), we replace atoms by the constant \( c \) at all the following positions: If the atom at this position in the instance \( e_i \rho \) is an atom with erased binder: \( a_{k,j} \) for some \( k \).

- An upper bound on the maximal number of binders for a single context-variable is \( |V_i| \ast d' \ast d' \) where \( d' \) is the number of context-variables in \( \Gamma_i \).

- Let \( \rho' \) be \( \rho \) after these modifications. The ground substitution \( \rho' \) is a solution of the state \( S_{i+1} \), and such that the same execution still leads to a final state that covers \( \rho' \).

The number of executions of rules (DCPref), (DCPrem) is at most the number of different context-variables. This holds, since (DCPref) removes one context-variable, and since (DCPrem) calls (DCFork), and (DCFork) can be applied also at most as often as there are expressions with topmost context-variables. As additional argument, all other rules keep the number of context-variables, and there is never a merge of two multisets that only contain context-variables. The estimation for the maximal number of variables is that in \((CAO(\pi_1 \cdot D_{1,1}) \rho)\), there can at most be \( d_i \ast |V_i| \) variables, where \( d_i \) is the number of context-variables in \( \Gamma_i \). Since there is an iterated multiplication, we obtain \(|V\alpha| \ast d_1 \ast d_2 \ast (d_2 - 1) \ast (d_1 - 1) \ast \ldots\), which leads to the estimation as claimed.

This change can be iterated until there are no (DCPref), (DCPrem)-steps having an index \( j \) where completely fresh variables are used for all context-variables in the multi-equation. Finally, we have constructed \( V\alpha_{\infty} \), and the modified solution \( \rho' \).

### A.6 The Algorithm NomUnifyASC for Restricted Input

> **Theorem 6.1.** The nominal unification problem in \( NL_{\alpha S} \) where freshness- and dvc-constraints are permitted in \( \nabla \), is solvable in polynomial time. Moreover, for a solvable
nominal unification problem \((\Gamma, \nabla)\), there exists a most general unifier of the form \((\nabla', \theta)\) which can be computed in polynomial time.

**Proof.** We assume that the algorithm computes in polynomial time a unifier \((\nabla', \theta)\) consisting of a substitution \(\theta\) and a constraint set \(\nabla'\), where in addition we assume that the output substitution \(\theta\) is represented in triangle-form and that it is of polynomial size (see [32] for the technique). Soundness and completeness of computing only a single execution path follows from Proposition 5.5 since there are no permutation-variables, and no context-variables.

For the final satisfiability test, we instantiate the expression-variables in the codomain of \(\theta\) with a constant from the signature. Note that also \(\lambda a.a\) could be used if there is no such constant. For expression-variables \(S\), it is possible to compute \(FA(S\theta)\) in polynomial time using dynamic programming. The bound atoms in \(FA(S\theta)\) are irrelevant, since these will be renamed by the substitution process which is done modulo \(a\). Then the check for every constraint \(dvc(e)\), whether \(e\theta\) satisfies the dvc, can be performed in polynomial time. ◀

### A.7 Expressivity of Freshness vs. DVC-Constraints

We show that there is a complexity jump between freshness constraints and dvc-constraints in the language \(NL_{aSC}\).

**Proposition A.3.** Satisfiability of a set \(\nabla\) of freshness constraints in \(NL_{aSC}\) can be decided in PTIME.

**Proof.** For deciding satisfiability, we apply the following transformations on \(\nabla\):

\[
\begin{align*}
& (a \neq b) \cup \nabla \rightarrow \nabla & (a \# f e_1 \ldots e_n) \cup \nabla \rightarrow (a \neq e_1, \ldots, a \neq e_n) \cup \nabla \\
& (a \neq \lambda b.e) \cup \nabla \rightarrow (a \neq e) \cup \nabla & (a \neq \lambda a.e) \cup \nabla \rightarrow \nabla \\
& (a \neq \pi : S) \cup \nabla \rightarrow \nabla & (a \neq \pi : D[e]) \cup \nabla \rightarrow \nabla
\end{align*}
\]

For most of the transformations \(\nabla \rightarrow \nabla'\) satisfiability of \(\nabla'\) obviously implies satisfiability of \(\nabla\). Hence, we only treat the exceptional cases. For the constraints \(a \neq \pi : S\), removal is correct, since \(S\) can be instantiated by a fresh atom, and for constraints \(a \neq (\pi : D)[e]\) removal is correct, since the set of conditions for a single \(D\)-variable is of the form \(\{a_1 \neq (\pi_1 : D)[e_1], \ldots, a_n \neq (\pi_n : D)[e_n]\}\) which can always be satisfied by instantiating \(D\) with \(\lambda a_1' \ldots a_n'\) where \(a_i' = \pi_i(a_i)\).

After exhaustively applying the transformation the constraint is either empty (and thus satisfiability is detected), or it contains a constraint \(a \neq a\) and unsatisfiability is detected. ◀

**Proposition A.4.** Satisfiability of a set of freshness and DVC-constraints in \(NL_{aSC}\) is NP-hard.

**Proof.** To show NP-hardness we reduce 3SAT to the satisfiability problem of freshness and non-capture constraints in \(NL_{aSC}\). Let \(C\) be a set of clauses. We generate a set of freshness and DVC-constraints \(T(C)\) as follows: Let us assume that \(True, False\) are fixed atoms. For every propositional variable \(p_j\) occurring in \(C\), there is a context-variable \(D_j\). The idea is that the instances of \(D_j\) are mainly \(\lambda True[.]\) or \(\lambda False[.]\). For each \(D_j\), we add a DVC-constraint \(dvc(f D_j(c)) (True False) \cdot D_j(c)\) to \(T(C)\), which ensures that the instance of \(D_j\) does not capture both \(True\) and \(False\).

For every clause \(\{L_1, L_2, L_3\} \in C\), the set \(T(C)\) contains a freshness constraint \(True \neq C_1[C_2[C_3[True]]]\) where \(C_i := D_j\) if \(L_i = p_j\) and \(C_i := \pi : D_j\) if \(L_i = \neg p_j\) where \(\pi = (True False)\). E.g., the clause \(\{\neg p_1, p_2, \neg p_3\}\) is encoded as \(True \neq (\pi : D_1)[D_2[\pi : D_3][True]]\).
We show that satisfiability of the input clause set is equivalent to satisfiability of the constructed constraint set:

If $C$ is satisfiable, then there exists a valuation $v$ which maps each variable $p_i$ to a truth value, s.t. in each clause at least one literal becomes $\text{True}$ under the valuation $v$. We set $\rho(D_i) := \lambda v(p_i).[\cdot]$. We have to show that the ground substitution $\rho$ satisfies all constraints in $T(C)$: For the dvc-constraints we get $\rho(f(D_j(c)(\text{True False}) \cdot D_j(c))) = f(\lambda v(p_i).c)(\lambda v(p_i).c)$ (where $\overline{L}$ negates a literal). Thus the dvc-constraints are satisfied by $\rho$. For each freshness constraint $\text{True} \# C_1[C_2[C_3[\text{True}]]]$ corresponding to clause $\{L_1, L_2, L_3\}$, we have $FA(\rho(C_1[C_2[C_3[\text{True}]]])) = \{\text{True}\} \setminus \{CA(\rho(C_1)) | 1 \leq i \leq 3\} = \{\text{True}\} \setminus \{v(L_i) | 1 \leq i \leq 3\} = \{\text{True}\} \setminus \{\text{True}\} = \emptyset$ since $v(L_i) = \text{True}$ must hold for at least one $L_i$ for $1 \leq i \leq 3$. Thus the freshness constraints $\text{True} \# C_1[C_2[C_3[\text{True}]]]$ hold.

For the other part, assume that $T(C)$ is satisfiable and $\rho$ is a ground substitution satisfying $T(C)$. The dvc-constraints ensure that $CA(\rho(D_j))$ cannot contain both $\text{True}$ and $\text{False}$, since otherwise binders in $\rho(D_j)$ and in $\rho((\text{True False}) \cdot D_j)$ cannot be pairwise disjoint. Since $\rho$ satisfies the freshness constraints, we have $\text{True} \notin FA(\rho(C_1[C_2[C_3[\text{True}]]]))$ for all $C_1, C_2, C_3$ corresponding to clause $\{L_1, L_2, L_3\}$, which implies that $\text{True} \in CA(\rho(C_1))$ for some $1 \leq i \leq 3$. Thus, for those $i$, we have $w \in CA(\rho(D_i))$ where $w = \text{True}$ if $L_i = p_j$ and $w = \text{False}$ if $L_i = \overline{p_j}$. This shows that each valuation which sets $v(p_j) := w$ for all such $p_j$ satisfies the clause $\{L_1, L_2, L_3\}$ and thus is a model of $C$. ◀
